Police spending and economic stabilization in a monetary economy with crime and differential human capital

Pengfei Jia* and King Yoong Lim**

This Version: December 22, 2018

Abstract

This paper presents a dynamic model with crime, differential human capital, credit market imperfection, and police spending to examine the role of the latter in stabilizing shock arisen from formal educational quality uncertainty. Based on a stylized parameterization, we find formal and illegal human capital accumulation to share a common cyclical property. There is a case for the use of a rule-based approach to police spending as it smoothens out the fluctuations arisen from formal educational uncertainty, while contributing to a “decoupling” of the two types of human capital. This nonetheless comes with a cost of greater propagation of the financial accelerator effect due to credit market imperfection, and therefore necessitates the use of a supplementary monetary smoothing regime to negate these negative effects.

Keywords: Crime, Credit Imperfection, Financial Accelerator, Human Capital Investment, Police Spending.

1 Introduction

Ever since the contributions of Becker (1968) and Ehrlich (1973), the socio-economic effects of crime have been a subject of both theoretical and empirical investigations by policymakers and economists alike. The macroeconomics literature on crime has examined the economic costs of crime mainly in a growth context, and largely established a negative crime-growth relationship over the long run (see, for instance, Imrohoroglu et al., 2004, 2006; Goulas and Zervoyianni, 2015). These studies also investigate and link crime to the different aspects of agents’ decisions and society, which include, non-exhaustively, child-rearing time (Neanidis and Papadopoulou, 2013), job-search and labour market institutions (Engelhardt et al., 2008), inequality (Kelly, 2000; Burdett et al., 2003), and human capital investment choice (Lochner and Moretti, 2004; Mocan et al., 2005). Of note, the latter introduced a framework that differentiates both formal/and crime-specific human capital—albeit not in a general equilibrium framework—bringing to light the intricate link between the two. However, the study stops short at exploring the economy-wide implications of the crime-education nexus, hence neglecting a key aspect associated with human capital investment in most developing economies with low educational attainment and high crime rate: private investment in formal human capital tends to be uncertain, an aspect already implied by various studies dated back to Galor and Zeira (1993).

Indeed, this shortcoming leads us to a general scarcity that remains in the existing analytical literature on macroeconomic analysis of crime: most models developed are independent from monetary and business-cycle considerations, despite studies such as Morrison et al. (2003) and Heinemann and Verner (2006) having documented that crime brings about macroeconomic multiplier effects and therefore, potentially greater economic fluctuations. Indeed, in both country-specific empirical studies (for instance, Detotto and Otranto, 2012; Pinotti, 2012; de Blasio et al., 2016 for Italy) and in the
sociological science literature in the tradition of Cantor and Land (1985), strong empiri-
cal links between business cycle fluctuations and crime incidence have been established,
albeit using mostly atheoretical framework (see, for instance, Arvanites and Defina,
2006; Bressler, 2009; Bushway et al., 2012). To our knowledge, save for a recent multi-
equations model by Astarita et al. (2018), a rigorous analytical framework with Keynes-
ian features remains elusive, more so a dynamic stochastic general equilibrium (DSGE)
framework of crime with business-cycle properties.

To preview, this paper develops a DSGE model in the broad “credit market imperfec-
tion” tradition of Bernanke and Gertler (1989) and Bernanke et al. (1999) to examine
the effects of human capital investment uncertainty in an economy with crime, police
spending (generally, public expenditure on public order and security), credit market
imperfections, and monetary policy. The latter duo are common features in “financial
accelerator” models, therefore allow for more realistic modeling of the impact of crime
on businesses and the wider economy, which in turn facilitate better understanding of
the macroeconomic stabilization properties of police spending, and how police spend-
ing interacts with the common macroeconomic stabilization tools. Indeed, given that
some of the economies with the highest crime rate in Latin America have experienced
decades of persistently high organized crime and monetary instability (see, for instance,
UNODC, 2012), there is a concrete policy need for such a model. This, together with
the well-documented uneven educational quality in the region\textsuperscript{1}, suggest that the inter-
actions of crime and formal human capital investment have a much significant effect on
the effectiveness of macroeconomic stabilization policies in these economies.\textsuperscript{2}

\textsuperscript{1}See, for instance, Agénor and Lim (p.34, 2018) for a discussion on the issues of overeducation in
the region. Despite that, on average, five of the most developed upper-income economies in the region
still register a 79.5 percent of non-tertiary workforce, suggesting an overall uncertain environment for
the attainment of formal/legal human capital.

\textsuperscript{2}According to Heinemann and Verner (2006) and Soares and Naritomi (2010), the non-homicidal and
non-domestic crimes in Latin America are predominantly urban crime, and a significant proportion of
these criminal activities are of semi-organized nature that have adverse impacts on firms and production
activities.
Indeed, the material costs of crime are estimated to add up to about 3.6 percent of GDP for Latin America (Londoño and Guerrero, 2000; Jaitman and Torre, 2017). Crime is said to consistently undermine business activities and therefore disincentivize human capital accumulation (Ayres, 1998). For the latter, Londoño and Guerrero (2000) estimate that the net accumulation of human capital in Latin America is half of what it ought to be due to the prevalence of crime. This, and given that education expansion has been shown empirically to have a crime-reducing effect (Machin et al., 2012), further reinforces the destabilizing impact of crime in the region. Indeed, it has been well-documented that organized criminal activities represent a non-negligible cost of doing business in the region, with the various downside risks resulting from organized crime often contributed to low business confidence, higher credit risk premium, and a greater overall business uncertainty when compared to other regions (Aravena and Solís, 2009; Spillan et al., 2014; Oguzoglu and Ranasinghe, 2017). All these create the needs for the governments to not just spend more on police and crime prevention (Bourguignon, 1999), but to find ways in improving its effectiveness. Indeed, according to Soares and Naritomi (2010), small police force is attributed to be a key factor of the high crime rate in Latin America. The relatively low level of government expenditure on public safety and small number of police personnel are illustrated in Figure 1. With many governments in developed economies, such as the United Kingdom, also currently debating on how best to manage the specific spending on public safety/police, the various issues underlined are well-worth examining.

Specifically, we build on the monetary model of Agénor and Alper (2012) to examine the nexus between crime and macroeconomic stability by exploring the interactions between organized crime and human capital (empirically well-documented in the Italian Mafia literature, but scarce in terms of analytical model). The nominal rigidities and monetary features are therefore included by design, as these are well-documented to be
the main drivers of the financial accelerator effect, which in turn affects the real credit cost—the lending risk premium of which depends on crime rate—faced by firms and its propagation mechanism.\(^3\) The rest of the paper is structured as follows. Section 2 presents the model. Section 3 defines and solves for its symmetric and steady-state equilibria. In Section 4, the model solutions are then log-linearized and parameterized to reflect a typical middle-income Latin American economy with high crime rates. Section 5 discusses the policy effects of the structural shocks introduced, especially on the role of public security/police spending in managing the fluctuations associated with formal human capital investment. Policy lessons drawn, together with future research directions, conclude the article in Section 6.

2 The Model

A closed economy populated by a continuum of identical infinitely-lived individuals, indexed by \(i \in (0, 1)\) is considered. Individuals consume, hold monetary assets, make human and physical capital investments, and allocate their time, normalized to one, among leisure, market works \((N_{it} \in (0, 1))\), and criminal activities \((\theta_{it} \in (0, 1))\). In market works, individuals supply effective labor hours \((H_{it}^Y N_{it})\) to a continuum of monopolistically competitive intermediate goods-producing firms (IG firms), indexed by \(q \in (0, 1)\), which supply the composite of intermediate goods to a final good-producing firm. In criminal activities, consistent with studies such as Gaviria (2002) and Blackburn et al. (2017), these take a quasi-organized form that has effects similar to imposing a tax (extortion, if interpreted as heavy crime; or swindling of firms’ resources, if interpreted as corporate crime) on the production of the intermediate goods (IGs) and therefore can\(^3\)For readers who are not interested in examining these credit risk–crime nexus and instead only want to focus on police spending, these features can be dropped from the model. However, the policy realism of only having only police spending in an economy without monetary policy is minimal, and therefore will not provide much concrete insights.
be treated as a type of marginal cost to the firms.\footnote{In practice, as described in Case Study-based contributions such as Aravena and Solís (2009) UNODC (2012), the characteristics of organized crime in Latin America can be quite different across the different economies, though a general specification is suffice to capture their impacts on firms in the context of this model.} By investing and owning the physical capital stock of the economy, individuals rent it to the IG firms, which in turn use it as collateral for borrowing from a commercial bank. Each IG firm employs effective labor and physical capital, while incurring additional marginal cost due to crime, to produce a perishable good, which is subject to the standard Rotemberg (1982) price adjustment process. Each individual $i$ owns an IG firm and therefore receives all the profits make by that firm. For simplicity, we assume $N_{it}^q = \theta_{it}^q = 0$, which means individuals do not work or commit fraud on own firms. There is full flexibility to wages which adjust to clear the labor market.

Individuals collectively own the commercial bank, which supplies credit at the prevailing loan rate only to the IG firms to finance their working capital needs. The bank also pays interest on individuals’ deposits and the liquidity from a Central Bank. The Central Bank supplies liquidity to the bank and purchases government bonds ($B_t^C$), with the corresponding liabilities being the money supply ($M_t^S$) and required reserves ($\Omega_t$). Monetary policy is operated by fixing the refinance rate ($i_t^R$) based on a reactionary Taylor-style (1993) policy rule, as in Liu (2006) and Agénor and Alper (2012). The government purchases the final good ($G_t^O$) and spend on public order and security ($G_t^P$). These are financed by taxing the income (both wage and capital income) of individuals at a constant rate, $\tau \in (0, 1)$, and the issuance of riskless one-period bonds, held by individuals and the Central Bank.

Similar to market works, it is the effective hours that count for criminal activities, which is dependent on crime-specific human capital ($H_t^C$), akin to a form of cultural capital. Unlike formal human capital, individuals do not have the choice to invest in crime-specific human capital, in line with Mocan et al. (2005). Each period, crime-specific
human capital gains by an exogenous amount $\Lambda$, but can be reduced by the government’s investment in maintaining public security ($G_t^P$). The probability of an individual escaping apprehension after committing a crime is given exogenously by $\pi \in (0, 1)$, in line with most macroeconomic studies on crime. If caught, individuals’ income is confiscated.

### 2.1 Individuals

Individuals $i \in (0, 1)$ derive utility from consumption ($C_{it}$), leisure, and a composite index of real monetary assets (real cash balances, $m_{it}$, and bank deposits, $d_{it}$). They solve the intertemporal optimization problem of maximizing

$$V^i_t = E_t \sum_{s=0}^{\infty} \beta^s \left[ \frac{(C_{it})^{1-\frac{1}{\sigma}}}{1-\frac{1}{\sigma}} + \eta_N \ln(1 - N_{it} - \theta_{it}) + \eta_F \ln(m_{it}^H d_{it}^{1-v}) \right]$$

subject to an end-of-period flow budget constraint of

$$\Delta M^H_{it} + \Delta D_{it} + \Delta F_{it} = P_t(r_t K_{it} + w_t H^Y_{it} N_{it}) + P_t[\pi H^C_{it} \theta_{it} (r_t K_{it} + w_t H^Y_{it} N_{it})] - T_{it} + i_{t-1}^D D_{it} - i_{t-1}^B B_{it}^H + J_{it}^G + \xi_{it} J_{it}^B - P_t(C_{it} + I_{it} + IH_{it})$$

where $r_t K_{it}$ is the total factor payments, $r_t$ the real rental price of capital, $w_t$ the economy-wide real wage, $T_{it}$ is the taxes paid to
the government, $M^{H}_{it} = P_t m^{H}_{it}$ the nominal cash holdings, $D_{it} = P_t d_{it}$ the nominal deposits, $B^{H}_{it} = P_t B^{H}_{it}$ the nominal holding of government bonds by individuals, $i^{P}_{t-1}D_{it-1}$ ($i^{P}_{t-1}B^{H}_{it-1}$) the interests on deposit (government bonds) hold in previous period, $I_{it}$ the investment in capital stock, $IH_{it}$ the investment in formal human capital, $J^{IG}_{it}$ the end-of-period profits received from IG firms, and $J^{B}_{it} (\xi_i \in (0, 1))$ the claim (fraction of the profits) hold by individual $i$ on the commercial bank. Individuals therefore hold nominal wealth in the form of nominal cash, deposits, government bonds, and real stock of physical capital ($K_{it}$) in firm $q = i$.

The stock of physical capital at the beginning of period $t + 1$ is given by

$$K_{it+1} = (1 - \delta^K)K_{it} + I_{it} - \Gamma(K_{it+1}, K_{it}), \quad (3)$$

where $\delta^K$ is the depreciation rate of physical capital and $\Gamma(K_{it+1}, K_{it})$ the standard (in the DSGE literature) capital adjustment cost,7

$$\Gamma(K_{it+1}, K_{it}) = \frac{\Theta_K}{2} \left[ \frac{K_{it+1}}{K_{it}} - 1 \right]^2 K_{it}, \quad \Theta_K > 0. \quad (4)$$

The formal and illegal human capital at period $t + 1$ evolves according to

$$\mathbb{E}_t H^Y_{it+1} = \Theta^N_t IH_{it} + (1 - \delta^L)H^Y_{it}, \quad \text{and} \quad (5)$$

$$\mathbb{E}_t H^C_{it+1} = \Lambda - \Theta^C_t G^P_t + (1 - \delta^C)H^C_{it}, \quad (6)$$

respectively, where $\delta^L, \delta^C \in (0, 1)$ is the formal, illegal human capital depreciation rate, $\Theta^N_t, \Theta^C_t > 0$ are the respective human capital investment efficiency for private individuals and government common to all individuals, and $\Lambda$ is a time-invariant additive

---

7This, together with the Rotemberg (1982) pricing introduced later, is incorporated as a generalized feature of a monetary economy. Both can easily be dropped from the model by setting the adjustment parameters to zero.
parameter for crime-specific human capital (that adds to the overall stock in each period as one continues to involve in crime), following Mocan et al. (2005). As novel features that further contribute to their framework, both investment efficiencies are dynamic parameters with both deterministic and stochastic components. Specifically, investment efficiency of formal human capital is given by

\[ \Theta_t^N = \Theta_0^N \left( \frac{H_C}{H_C} \right)^{-\varphi_N}, \]  

where \( \varphi_N \geq 0, \Theta_0^N = (\Theta_0^N)^{1-\varsigma_N} (\Theta_{0t-1}^N)^{\varsigma_N} \exp(\epsilon_t^N) \) follows an AR(1) process, in which \( \Theta_0^N > 0, \varsigma_N \in (0, 1) \) is the associated autoregressive coefficient, and \( \epsilon_t^N \) is normally distributed with zero mean and a constant variance \( (\sigma_N^2) \). The issue of uncertainty in formal human capital investment is explored in various macroeconomic studies in the tradition of Galor and Zeira (1993), mainly in deterministic framework, where human capital investment is endogenized to factors such as credit constraint and unobserved income [see, for instance, Galor and Moav (2004)]. In an economy where crime is a main part of economic activities, it can be argued that formal human capital investment efficiency is adversely affected by the society’s receptiveness towards crime, while the stochastic component is similar to Agénor (2016).

To model the link between relative deprivation and crime (Hicks and Hicks, 2014), we utilize a “scale effect” specification for the (cultural) crime-specific human capital investment efficiency,

\[ \Theta_t^C = \Theta_0^C \left( \frac{\theta_t}{\theta} \right)^{-\varphi_C}, \]  

where \( \varphi_C \geq 0, \Theta_0^C = (\Theta_0^C)^{1-\varsigma_C} (\Theta_{0t-1}^C)^{\varsigma_C} \exp(\epsilon_t^C), \Theta_0^C > 0, \varsigma_C \in (0, 1), \) and \( \epsilon_t^C \sim N(0, \sigma_C^2). \)

\(^8\)Alternatively, a partial-equilibrium job-search mechanism in similar vein of Burdett et al. (2003), Engelhardt et al. (2008), Engelhardt (2010) can be introduced that posits human capital investment efficiency as being derived from a job-search process, the cost of which is adversely affected by the stock of crime-specific human capital in the economy. This then leads to a first-order condition that is similar to (??), at the cost of increasing the model size with very little gained in terms of what is not already known in the existing literature. We therefore abbreviate this and use a seemingly ad-hoc feature.
As such, while crime-specific human capital accumulation in itself is uncertain, the relativity of the crime rate from a “natural” rate implicitly reflects the state of relative deprivation in the economy, and therefore affecting the effectiveness of government’s crime-combatting measures.

Each household $i$ maximizes lifetime utility by choosing $C_{it}$, $N_{it}$, $\theta_{it}$, $m_{it}^H$, $b_{it}^H$, $d_{it}$, $K_{it+1}$, and $H_{it+1}^Y$, taking prices (and therefore inflation rates, $\pi_{t+1} = (P_{t+1} - P_t)/P_t \forall t$), factor returns, tax rate, $i^D_t$, $i^B_t$, and the crime-specific human capital levels, $H_{it}^C \forall t$ as given. As shown in Appendix A, solving the intertemporal utility maximization problem gives the following first-order conditions for individuals:

$$E_t\left(\frac{C_{it+1}}{C_{it}}\right)^{1/\sigma} = \beta E_t\left(\frac{1 + i^B_t}{1 + \pi_{t+1}}\right),$$  \hspace{1cm} (9)

$$N_{it} - \theta_{it} = \frac{(1 - \tau_N)}{\kappa H_{it}^C} - \frac{r_t K_{it}}{w_t H_{it}^Y},$$  \hspace{1cm} (10)

$$\frac{\eta_NC_{it}^{1/\sigma}}{\kappa H_{it}^C (r_t K_{it} + w_t H_{it}^Y N_{it})} = \frac{\eta_NC_{it}^{1/\sigma}}{(1 + \kappa H_{it}^Y \theta_{it} - \tau_N)w_t H_{it}^Y},$$  \hspace{1cm} (11)

$$m_{it}^H = \frac{\eta_F u_{it}^{C_{it}} (1 + i^B_t)}{i^B_t - i^D_t},$$  \hspace{1cm} (12)

$$d_{it} = \frac{\eta_F(1 - \nu)C_{it}^{1/\sigma} (1 + i^B_t)}{i^B_t - i^D_t},$$  \hspace{1cm} (13)

$$E_t\left(\frac{1 + i^B_t}{1 + \pi_{t+1}}\right) = E_t\left\{1 + \Theta_K \left(\frac{K_{it+1}}{K_{it}} - 1\right)\right\}^{-1} \left[\left(1 + \kappa H_{it+1}^C \theta_{it+1} - \tau_K\right)r_{t+1}\right. + \left.(1 - \delta^K) + \Theta_K \frac{\Delta K_{it+2}^2}{2} \right\},$$  \hspace{1cm} (14)

$$E_t\left(\frac{1 + i^B_t}{1 + \pi_{t+1}}\right) = E_t \left[\Theta_t^N (1 + \kappa H_{it+1}^C \theta_{it+1} - \tau_N)w_{t+1} N_{it+1} + (1 - \delta^L),\right.$$

$$E_t \left[\left(1 + \kappa H_{it+1}^C \theta_{it+1}\right) (\Theta_t^N w_{t+1} N_{it+1} - \frac{r_{t+1}}{\Xi_K}) - \tau_N \Theta_t^N w_{t+1} N_{it+1} + \tau_K \frac{r_{t+1}}{\Xi_K}\right]$$  \hspace{1cm} (16)

where $\Xi_K = 1 + \Theta_K \left(\frac{K_{it+1}}{K_{it}} - 1\right)$, illegal human capital, $H_{it+1}^C$, being given by (6), and the transversality conditions, $\lim_{s \to \infty} E_{t+s}^\gamma \lambda_{t+s}(\xi_{ht+s}/P_{t+s}) = 0$, for $\xi = K, m^H$ hold.
Without capital adjustment cost ($\Theta_K = 0$), (14) and (16) can be written as:

$$
E_t\left(\frac{1 + i^B_t}{1 + \pi_{t+1}}\right) = E_t\left[(1 + \kappa H^C_{it+1}\theta_{it+1} - \tau_K)\tau_{t+1}\right] + (1 - \delta^K), \quad \text{and} \quad (17)
$$

$$
E_t\left[(1 + \kappa H^C_{it+1}\theta_{it+1})(\Theta_i^N w_{it+1}N_{it+1} - r_{t+1})\right] = (\delta^L - \delta^K). \quad (18)
$$

### 2.2 Final Good sector

The final good, $Y_t$, is produced by a zero profit-making, perfectly competitive representative firm that assembles a continuum of intermediate goods, $Y_{qt}$, $q \in (0, 1)$, using standard Dixit-Stiglitz (1977) technology. Specifically, the profit maximization problem is given by $Y_{qt} = \text{arg max } P_t \{ \int_0^1 [Y_{qt}]^{(\kappa-1)/\kappa}dj\}^{\kappa/(\kappa-1)} - \int_0^1 P_{qt}Y_{qt}dj$, where $\kappa > 1$. For a given IG price $P_{qt}$, yields the demand function for each intermediate good,

$$
Y_{qt} = \left(\frac{P_{qt}}{P_t}\right)^{-\kappa}Y_t, \quad \forall q \in (0, 1), \quad (19)
$$

and the corresponding final price, $P_t = \{ \int_0^1 [P_{qt}]^{1-\kappa}dj\}^{1/(1-\kappa)}$.

### 2.3 Intermediate Goods sector

Using constant returns-to-scale production technology, each IG firm $q \in (0, 1)$ employs physical capital, $K_{qt}$, and labor (in effective human capital-adjusted terms, $H^Y_{qt}N_{qt}$, supplied by individual $i$, $q = i$) and faces the production function,

$$
Y_{qt} = A_t K_q^\alpha (H^Y_{qt}N_{qt})^{1-\alpha}, \quad (20)
$$

where $\alpha \in (0, 1)$, and $A_t$ denotes a common economy-wide technology shock following an AR(1) process, $A_t = (A_0)^{1-\kappa_A}\exp(\epsilon_A^t)$, where $\epsilon_A^t$ is normally distributed with zero mean and a constant variance ($\sigma_A^2$). Each IG firm $q$ solves a two-stage profit maximization problem: a static unit cost minimization problem, followed by an intertemporal profit maximization problem due to a Rotemberg (1982) style price-adjustment cost.
Following Ravenna and Walsh (2006), IG firm $q$ borrows from the commercial bank to pay wages to effective labor hours in advance. Let $L_{qt}$ be the amount borrowed, the financing constraint is given by

$$l_{qt} = \frac{L_{qt}}{P_t} \geq w_t H_{qt}^Y N_{qt}. \tag{21}$$

At the end of the period, the loan is repaid at a gross nominal loan rate $(1 + i_{qt}^L)$. In each period $t$, each IG firm $q$ therefore incurs a cost of $(1 + i_{qt}^L)w_t$ for effective labor hired from a competitive labor market and the rate of returns, $r_t$ for physical capital hired. In addition, consistent with the urban crime described in studies such as Londoño and Guerrero (2000), each IG firm also faces extortions from criminals (the amount of resources extorted depends on the effective hours of crime, $\theta_{qt} H_{qt}^C$, committed by individual $j$, $q = j$)\(^9\) at a constant probability $\pi_V$, hence incurring an additional production cost, $\theta_{qt} H_{qt}^C[w_t H_{qt}^Y N_{qt} + r_t K_{qt}]$. This specification is also consistent with many organized crime described in Latin America-based studies such as Gaviria (2002) and Gomez Soler (2012). For simplicity, we assume $\pi_V = 1$.\(^{10}\) Each firm $q$ therefore solves the unit cost minimization problem,

$$\min_{N_{qt}, K_{qt}} (1 + i_{qt}^L)w_t H_{qt}^Y N_{qt} + r_t K_{qt} + \theta_{qt} H_{qt}^C[w_t H_{qt}^Y N_{qt} + r_t K_{qt}],$$

subject to $Y_{qt} = 1$, taking wages, rate of returns of capital, and effective of hours of crime as given. The first-order conditions derived in Appendix A. The implied physical

---

\(^9\)We assume individuals neither work nor extort from the IG firm they own, $N_{iq}^q = \theta_{iq}^q = 0$. Similarly, we also assume that, while $j$ belongs to the continuum $i \in (0, 1)$, $i \neq j$. In other words, an individual $i$ does not extort from the same firm he is working in.

\(^{10}\)Such victimization probability can be referred to Imrohoroglu et al. (2004, 2006), though they model crime as theft. In this article, we model crime as direct extortions from firms, as in Blackburn et al. (2017). In stationary equilibrium, the victimization probability would then equal economy-wide crime rate, $\bar{\theta}$. We abstract from this by assuming $\pi_V = 1$. 

12
capital-effective labor ratio of each firm $q$ is given by

$$
\frac{K_{qt}}{H_{qt}^Y N_{qt}} = \frac{\alpha}{1 - \alpha} \frac{(1 + i_{qt}^L + \theta_{qt} H_{qt}^C)w_t}{(1 + \theta_{qt} H_{qt}^C)r_t},
$$

(22)

where the marginal cost of both labor and physical capital includes the amount lost to crime. Specifically, from Appendix A, the derived unit real marginal cost is given by:

$$
m_{cq}t = \frac{[(1 + i_{qt}^L + \theta_{qt} H_{qt}^C)w_t]^{1-\alpha}[(1 + \theta_{qt} H_{qt}^C)r_t]^\alpha}{\alpha^\alpha(1 - \alpha)^{1-\alpha}}.
$$

(23)

In addition to the marginal cost, each firm $q$ also incurs price-adjustment cost due to nominal price stickiness, which takes the form of

$$
\frac{\Theta_F}{2} \left( \frac{P_{qt}}{(1 + \tilde{\pi})P_{qt-1}} - 1 \right)^2 Y_t,
$$

where $\Theta_F \geq 0$ is the parameter measuring the degree of price stickiness and $\tilde{\pi}$ is the steady-state inflation rate. With this, each IG firm $q$ selects a sequence of prices, $\{P_{qt+s}\}_{s=0}^{\infty}$ so as to maximize the total discounted sum of all the firm’s real profits, as in:

$$
\max_{\{P_{qt+s}\}_{s=0}^{\infty}} E_t \sum_{s=0}^{\infty} \beta^{s}\lambda_{t+s} \left( \frac{\Pi_{qt+s}}{P_{t+s}} \right),
$$

(24)

where the discount factor is the same as the individuals (since they own the IG firms) and the nominal profits, $\Pi_{qt}$, is given by

$$
\Pi_{qt} = P_{qt}Y_{qt} - P_t m_{cq}t Y_{qt} - \frac{\Theta_F}{2} \left( \frac{P_{qt}}{(1 + \tilde{\pi})P_{qt-1}} - 1 \right)^2 P_t Y_t.
$$

(25)
Substitute (19) into (25), the first-order condition can be expressed as

\[
(1 - \varsigma) \lambda_t \left( \frac{P_{qt}}{P_t} \right)^{-\varsigma} \left( \frac{Y_t}{P_t} \right) + \lambda_t \varsigma \left( \frac{P_{qt}}{P_t} \right)^{-\varsigma - 1} \frac{Y_t m c_{qt}}{P_t} 
- \lambda_t \Theta_F \left\{ \left( \frac{P_{qt}}{(1 + \frac{\Theta_F}{P_{qt-1}})} - 1 \right) \times \frac{Y_t}{(1 + \frac{\Theta_F}{P_{qt-1}})} \right\} + \beta \Theta_F E_t \left\{ \lambda_{t+1} \left( \frac{P_{qt+1}}{(1 + \frac{\Theta_F}{P_{qt+1}})} - 1 \right) \times \left( \frac{P_{qt+1}}{(1 + \frac{\Theta_F}{P_{qt+1}})} Y_{t+1} \right) \right\} = 0,
\]

which, in the absence of price stickiness ($\Theta_F = 0$), is merely a simple mark-up pricing of

\[
P_{qt} = \frac{\varsigma}{\varsigma - 1} m c_{qt} P_t.
\]
where \( q \) is the repayment probability. Solving this yields the first-order conditions:

\[
i_t^D = (1 + \frac{1}{\eta_D})^{-1}(1 - \mu) i_t^R, \quad \text{and} \quad i_{qt}^L = (1 + \frac{1}{\eta_L})^{-1} i_{qt}^R,
\]

(29)

where \( \eta_D = [\partial D_t/\partial i_t^D] \cdot (i_t^D / D_t) > 0 \) and \( \eta_{L_q} = [\partial L_t/\partial i_{qt}^L] \cdot (i_{qt}^L / L_t) < 0 \) are the interest elasticity of deposit supply and the interest elasticity of loan demand respectively. The latter is conceptually speaking different for each IG firm \( q \), but can be assumed to be the same across the firms in the symmetric equilibrium examined later.

Assuming the supply of deposit is perfectly elastic (\( \eta_D \) assumes a large value), the optimal deposit rate, \( i_t^D \), is then:

\[
i_t^D = (1 - \mu) i_t^R.
\]

(30)

As argued in Agénor and Montiel (2008), the repayment probability generally increases with the collateral provided, \( \kappa P_t K_{qt} \), \( \kappa \in (0, 1) \), as a percentage of the loan taken out by firms. In addition, in line with the thesis of crime being extortion on firms, we also specify it to depend negatively on a macro-environment factor, in the form of the economy-wide crime rate, \( \theta_t \), in consistent with Baumann and Frieh (2017). The repayment probability therefore takes the form of \( q = q_0[1 + \Psi_{qt}(\kappa P_t K_{qt}/L_{qt}; \theta_t)]^{-1} \), which, combined with (29), yields

\[
i_{qt}^L = (1 + \frac{1}{\eta_{L_q}})^{-1} q_0^{-1}[1 + \Psi_{qt}(\kappa P_t K_{qt}/L_{qt}; \theta_t)]^{-1} i_t^R,
\]

where \( \Psi_{qt} > 0, \Psi_{qt}'(\kappa P_t K_{qt}/L_{qt}) < 0, \Psi_{qt}'(\theta_t) > 0 \) is the risk premium the bank charges on its lending to firms. Specifically, if \( \Psi_{qt} = \Psi_0(\kappa P_t K_{qt}/L_{qt})^{-\phi_1(\theta_t)^{\phi_2}}, \Psi_0, \phi_1, \phi_2 \geq 0 \), we have

\[
i_{qt}^L = (1 + \frac{1}{\eta_{L_q}})^{-1} q_0^{-1}[1 + \Psi_0(\kappa P_t K_{qt}/L_{qt})^{-\phi_1(\theta_t)^{\phi_2}}]^{-1} i_t^R,
\]

(31)
At the end of the period, the commercial bank makes a net profit of

$$J_t^B = (1 + i_{qt}^L) L_t - (1 + i_t^D) D_t - (1 + i_t^R) L_t^B,$$

which are paid in equal shares to the individuals.

### 2.5 Central Bank

The central bank sets the monetary policy. It holds government bonds, $B_t^C$, and loans to the commercial bank, $L_t^B$, as assets. Its liabilities consist of the currency, $M_t^S$, and the required reserves, $\Upsilon_t = \mu D_t$. From the balance sheet of the central bank, the currency in circulation can be determined as:

$$M_t^S = L_t^B + B_t^C - \mu D_t.$$  \hspace{1cm} (33)

The net income made on loans to the commercial bank is transferred to the government at the end of each period.

The monetary policy is operated by fixing the refinance rate, $i_t^R$, assumed to be determined by a Taylor-type (1993) policy rule. The linearized form is given by

$$i_t^R = \epsilon_t (i_{t-1}^R)^\omega \left[(\tilde{\rho} + \tilde{\pi})(1 + \pi_t \gamma_1 \gamma_2)^1 - \omega, \right]$$  \hspace{1cm} (34)

where $\epsilon_t$ denotes another structural shock with an AR(1) process, $\epsilon_t = (\epsilon_0)^{1 - \zeta M} (\epsilon_{t-1}^\zeta M \exp(\epsilon_t))$, where $\zeta_t$ is normally distributed with zero mean and a constant variance ($\sigma_M^2$) (see Rudebusch (2006)). The specification is in line with the empirical finding of Moura and Carvalho (2010), in that monetary policy-setting in developing economies tend to be reactionary. Likewise, the introduction of a source of random shock to the interest rate-setting is in consistent to the “speed limit” policy approach introduced in Liu (2006) and
Agénor and Alper (2012), and reinforces the reactionary nature of the characteristics of monetary policy in developing economies.

2.6 Government

The government issues nominal riskless one-period bonds to the central bank and individuals. It also taxes both labor and capital income at a constant rate, \( T_t = \tau_K r_t K_{it} + \tau_N w_t H_{it}^YN_{it} \). The government also receives the illegal income confiscated from successfully apprehending a criminal, and the net income \( (i_t^R L_t \text{ and } i_t^B B_{t-1}^C) \) transferred from the central bank. These are used to finance the purchases of final good \( (G_O^t) \) and an investment expenditure on improving public order and security \( (G_P^t) \).\(^{11}\) The budget constraint is given by

\[
P_t[(1 - \lambda)H_{it}^C \theta_{it}(r_t K_{it} + w_t H_{it}^YN_{it})] + P_t T_{it} + B_t^H + B_t^C \tag{35}
\]

\[
= (1 + i_{t-1}^B)(B_{t-1}^H + B_{t-1}^C) + P_t(G_P^t + G_O^t) - i_t^R L_t - i_{t-1}^B B_{t-1}^C.
\]

Government purchases are assumed to be a constant fraction of output, hence \( G_O^t = \nu_O Y_t, \nu_O \in (0, 1) \). The expenditure on public order and security, \( G_P^t \), is the novel feature whose properties is examined in this article. For the benchmark case, we assume \( G_P^t \) to be set also at a constant fraction of output, \( G_P^t = \nu_P Y_t \), where the spending share \( \nu_P \in (0, 1) \) is chosen at the discretion of the government. For comparison, we also consider a case that is rule-based, where \( G_P^t = G_P^0(\psi_1)_{t, \psi} \), \( \psi_1 \geq 0 \), which essentially turns the expenditure on public order and security to a reaction function that depends on the relative crime rate, \( \theta_t \), from its steady-state value.

\(^{11}\)It is debatable whether the expenditure on improving public order and security is treated as a consumption or investment expenditure. Given our specification where it contributes to the “de-accumulation” of crime-specific human capital, it is akin to a type of investment expenditure.
3 Symmetric and Steady-state Equilibrium

Definition 1: A symmetric equilibrium is where all individuals and all IG firms are identical. This means, for all individuals \( i \in (0, 1) \), \( C_{it} = C_t \), \( \theta_{it} = \theta_t \), \( N_{it} = N_t \), \( K_{it} = K_t \), \( I_{it} = I_t \), \( IH_{it} = IH_t \), \( M^H_{it} = M^H_t \), \( B^H_{it} = B^H_t \), \( D_{it} = D_t \), \( K_{it} = K_t \). For all IG firms \( q \in (0, 1) \), \( P_{qt} = P_t \), \( mc_{qt} = mc_t \), \( K_{qt} = K_t \), \( N_{qt} = N_t \), \( \theta_{qt} = \theta_t \). All individual and aggregate behaviors are consistent, which means all individual- and firm-specific human capital equal the economy-wide average level of human capital, that is, \( H^Y_{\varphi t} = H^Y_t \), \( H^C_{\varphi t} = H^C_t \), where \( \varphi = i, q \). All firms produce the same output and prices and marginal costs are the same across firms. By implications, the loan rate, \( i^L_{qt} \), and the interest elasticity of loan demand, \( \eta_{Lq} \), and the risk premium are the same across firms, \( i^L_{qt} = i^L_t \), \( \eta_{Lq} = \eta_L \), \( \Psi_{qt} = \Psi_t \), \( \forall q \). From (25), real profit of a representative IG firm is therefore \( (1 - mc_t)Y_t - 0.5\Theta_F[1/(1 + \pi) - 1]^2 \), with \( \pi \) denoting the steady-state inflation rate. These would also allow us to simplify the first-order condition of the intertemporal profit maximization problem of a representative IG firm, (26), to

\[
(1 - \varsigma) + \varsigma mc_t - \Theta_F \left\{ \frac{1 + \pi_t}{1 + \pi} - 1 \right\} \left( \frac{1 + \pi_t}{1 + \pi} \right) + \Theta_F E_t \left\{ \frac{1 + \pi_{t+1}}{1 + \pi} \left( \frac{1 + \pi_{t+1}}{1 + \pi} - 1 \right) \left( \frac{1 + \pi_{t+1}}{1 + \pi} \right) \right\} = 0. \tag{36}
\]

The deposit, credits, currency, government bonds, and goods markets are in equilibrium. The supply of deposits by households and the supply of loans by the commercial bank are perfectly elastic at the prevailing rates, hence the two markets are always clear. For the currency market, the equilibrium condition is \( M^S_t = M^H_t + M^F_t \), where \( M^F_t = \int_0^1 M^F_{qt} dq \) is firms’ total cash-holdings. Assuming that the bank loans to firms are made only in currency form, \( L_t = M^F_t \), using (28) and (33), we can eliminate \( L^B_t \) to get

\[
M^H_t + D_t = B^C_t. \tag{37}
\]
Further, by using the aggregate expressions of (12) and (13), we can write an expression for the real value of central bank’s holding of government bonds:

\[ b^C_t = \frac{B^C_t}{P_t} = \eta_F (C_t)^{1/\sigma} \left( 1 + i^B_t \right) \left\{ \frac{\nu}{i^B_t} + \frac{1 - \nu}{i^B_t - i^D_t} \right\}. \]  

(38)

Given this, and knowing that \( P_t/P_{t-1} = 1 + \pi_t \), using the government budget constraint from (35), we solve for the real value of the total stock of government bonds outstanding, \( b_t \):

\[ b_t = \left( \frac{1 + i^B_{t-1}}{1 + \pi_t} \right) b^H_{t-1} + \frac{b^C_t}{1 + \pi_t} + G^P_t + G^O_t + i^R_t \]

\[ - [(1 - \varepsilon) H^C_t \theta_t + \tau_K] r_t K_t - [(1 - \varepsilon) H^C_t \theta_t + \tau_N] w_t H^Y_t N_t, \]

with the individuals’ holding of government bonds determined by \( b^H_t = b_t - b^C_t \). Lastly, the goods market equilibrium is given by

\[ Y_t = C_t + G^P_t + G^O_t + I_t + \frac{\Theta_F}{2} \left( \frac{1 + \pi_t}{1 + \bar{\pi}} - 1 \right)^2 Y_t, \]  

(40)

where \( C_t = \int_0^1 C_{it} di \), and \( I_t = \int_0^1 I_{it} di \) is given by (3). For the benchmark case where \( G^P_t = v_P Y_t \), the aggregate resource constraint of (40) can be rewritten as

\[ \left\{ 1 - (v_O + v_P) - \frac{\Theta_F}{2} \left( \frac{1 + \pi_t}{1 + \bar{\pi}} - 1 \right)^2 \right\} Y_t = C_t + K_{t+1} - (1 - \delta^K) K_t + \frac{\Theta_K}{2} \left[ \frac{K_{t+1}}{K_t} - 1 \right] K_t. \]  

(41)

Finally, note that (22), given \( P_t \), can be used to determine both the economy-wide real and nominal wages:

\[ w_t = \frac{W_t}{P_t} = \frac{1 - \alpha}{\alpha} \frac{(1 + \theta_t H^C_t) r_t K_t}{(1 + i^L_t + \theta_t H^C_t) H^Y_t N_t}. \]  

(42)
**Definition 2:** A *steady-state equilibrium* of this economy is a stationary symmetric equilibrium in which, for a given set of parameters, a probability of escaping apprehension ($\pi$), and a set of policy arrangements $\{\mu, \tau, \nu_O, \nu_P\}$: (i) the endogenous variables $(\tilde{C}, \tilde{N}, \tilde{\theta}, \tilde{M}^H, \tilde{B}^H, \tilde{D}, \tilde{\check{K}}, \tilde{H}^Y, \tilde{H}^C, \tilde{B}^C, \tilde{Y})$ are constant $\forall t$; (ii) the prices, wages and rates $(\tilde{P}, \tilde{\check{r}}, \tilde{\check{w}}, \tilde{i}^B, \tilde{i}^D, \tilde{i}^L, \tilde{i}^R)$ are all constant $\forall t$; and by implications, (iii) the inflation ($\tilde{\pi}$), profits and marginal costs are constant $\forall t$. In addition, in the steady-state, the physical capital and goods’ prices fully adjust, which means the relevant adjustment costs equal zero ($\Theta_F = \Theta_K = 0$). The steady-state inflation rate also equals its target value ($\tilde{\pi} = \pi^T$).

We solve for the steady-state equilibrium in Appendix B. Without losing any generality, we solve for a simplified case where the inflation target is zero. As derived in Appendix B, we obtain the standard Fisher relationship, $\tilde{i}^R = \tilde{\check{r}} + \tilde{\pi}$. When $\tilde{\pi} = \pi^T = 0$, the steady-state refinancing rate ($\tilde{i}^R$) equals the real interest rate ($\tilde{\check{r}}$), which in this monetary economy with credit financing and criminal extortions, is negatively dependent on the steady-state level of effective crime rate ($\tilde{H}^C \tilde{\theta}$):

$$\tilde{\check{r}} = \frac{\beta^{-1} - (1 - \delta^K)}{(1 + \kappa \tilde{H}^C \tilde{\theta} - \tau)}.$$

(43)

In turn, the steady-state crime rate, $\tilde{\theta}$, is determined by:

$$\tilde{\theta} = (\kappa \tilde{H}^C)^{-1} \left[ \frac{(\delta^L - \delta^K)}{(\tilde{\Theta}^N \tilde{\check{w}} \tilde{N} - \tilde{\check{r}})} + \frac{\tilde{\Theta}^N \tau_N \tilde{\check{w}} \tilde{N}}{(\tilde{\Theta}^N \tilde{\check{w}} \tilde{N} - \tilde{\check{r}})} - \frac{\tau_K \tilde{\check{r}}}{(\tilde{\Theta}^N \tilde{\check{w}} \tilde{N} - \tilde{\check{r}})} \right],$$

(44)

which depends on the efficiency of investment in legal human capital ($\tilde{\Theta}^N$), the wage rate ($\tilde{\check{w}}$), real interest rate ($\tilde{\check{r}}$), tax rates ($\tau_N, \tau_K$), and the difference between the depreciation rate of human and physical capital ($\delta^L - \delta^K$). If $\tilde{\Theta}^N \tau_N \tilde{\check{w}} \tilde{N} = \tau_K \tilde{\check{r}}$, then the assumption of $\delta^L > \delta^K$ is needed to ensure positive crime rate in the steady state.

In the steady-state, crime-specific human capital ($\tilde{H}^C$) is a function of the steady-
state value of government spending on public order and security, and the corresponding spending efficiency in reducing crime-specific (cultural) human capital. Also, when $\bar{\tau} = 0$, the steady-state gross rate of return for government bonds equals the rate of time preference, $1 + \bar{r}^B = \frac{1}{\beta}$, which then determines the steady-level of real currency- and deposit-date of individuals.

For the steady-state solutions to be properly defined, as in when individuals hold $\tilde{d} \geq 0$ of real deposits, given that $\tilde{i}^D = (1 - \mu)\tilde{r}$, we must have $\tilde{r} < (1 - \beta)/(1 - \mu)$. Without price-adjustment cost, the marginal cost of IG firms in the steady state, even when there is non-zero cost arisen from criminal extortions, is equal to the standard mark-up condition of monopolistically competitive firms, $\tilde{mc} = \frac{\zeta - 1}{\zeta}$. The equations for other endogenous variables can be referred to in Appendix B. In summary, the simultaneous equations system characterizing the steady-state equilibrium of this model is consisting of 18 endogenous variables in real terms ($\tilde{r}, \tilde{i}^B, \tilde{i}^D, \tilde{w}, \tilde{H}^Y, \tilde{H}^C, \tilde{N}, \tilde{\theta}, \tilde{m}^H, \tilde{d}, \tilde{l}, \tilde{Y}, \tilde{K}, \tilde{b}^H, \tilde{b}^C, \tilde{C}, \tilde{G}^P$). Given the presence of the four stochastic shocks, to solve the model, we log-linearize the behavioral equations and the aggregate resource constraints around the non-stochastic, zero-inflation steady state.

4 Illustrative Parameterization

It is well-documented that the quality of crime data is generally poor, even for the well-used dataset of United Nations Survey of Crime Trends and Operations of Criminal Justice Systems (UN-CTS). This is especially true for Latin America, where under-reporting of crime remains prevalent (Fajnzylber et al., 1998; Rubio, 2000; Jaitman and Torre, 2017). This, coupled with the non-availability of quarterly data for variables such as human capital and time allocation, means a Bayesian estimation strategy is impractical. Against this backdrop, we calibrate the model with empirical parameterization...
using available statistics (as much as possible), so as to calibrate illustratively a typical middle-income Latin American economy where crime remains prevalent. Unless specified otherwise, all calibrations are implemented to obtain initial steady-state values for the endogenous variables that match the first moment of the long-term averages of the 21 non-British caribbean, Latin American economies for the period 1991-2016.\footnote{These include Argentina, Bolivia, Brazil, Chile, Colombia, Costa Rica, Cuba, Dominican Republic, Ecuador, El Salvador, Guatemala, Haiti, Honduras, Mexico, Nicaragua, Panama, Paraguay, Peru, Puerto Rico, Uruguay, and Venezuela.}

The parameter values are summarized in Table 1. Given the annual time frequency and developing country context, the discount factor is set at $\beta = 0.952$, which corresponds to an annual interest rate of 5 percent. With $\bar{r}^B = \frac{1}{\beta} - 1$ in steady state, we have the steady-state bond rate, $\bar{r}^B = 0.05$. The intertemporal elasticity of substitution, $\sigma$, and the preference parameter for leisure, $\eta_N$, are set at 0.6 and 1.75 respectively, consistent with the values commonly used for the Latin American economies (see Agénor and Montiel, 2015). The preference parameter for composite monetary assets, $\eta_F$, is set at a very low value of 0.02 to reflect a low utility derived from holding monetary assets (given that criminal activities provide an alternative outlet to generate income), which coincides with the value used in Agénor et al. (2014). The share parameter in the index of money holdings, $v$, is set at 0.2, which is based on the estimated cash-deposit ratio for our sample economies. For convenience, we set both the tax rates to be equal, $\tau_K = \tau_N = 0.2$, in the benchmark case, which is within range of the average marginal income tax rates for our sample economies.

In terms of the initial steady-state values for the time allocation variables, a standard 8 hours of formal market work would give $\bar{N} = 8/24 = 0.33$. The time allocated to criminal activities ($\bar{\theta}$) has to be estimated. Based on the methodology of Neanidis and Papadopoulou (2013), we estimate $\bar{\theta}$ based on average crime incidence for our sample economies using the UN-CTS dataset, which yields approximately 0.167 (per 100,000
inhabitants). We therefore set $\tilde{\theta} = 0.167$. The exogenous probability of escaping apprehension, $\varpi$, is set at 0.7, which is consistent with the UN-CTS dataset-based estimates of Neanidis and Papadopoulou (2013) and Jia et al. (2018). Using the IMF Government Financial Statistics, we can easily calculate the constant parameters for expenditure on public order and security ($v_P$) and other government consumption ($v_O$). For our sample Latin American economies, we have $v_P = 0.0157$ and $v_O = 0.167$.

Next, we consider human capital. Following Mocan et al. (2005), we set the depreciation rate for both types of human capital, $\delta^L = \delta^C = 0.05$. The calibration of the remaining parameter, $\Lambda$, as well as the determination of the two time-varying endogenous human capital investment efficiency values ($\tilde{\Theta}^N$ and $\tilde{\Theta}^C$) are as follows. First, to satisfy $\delta^L > \delta^K$, we assume physical capital has a lower depreciation rate than human capital, and set $\delta^K = 0.02$ (a value in line with Agénor et al. (2014)). Given this and other parameter values, from (43), we can determine the value of the composite term, $\varpi \tilde{H}^C \tilde{\theta} = 1.4$. With $\varpi = 0.7$ and $\tilde{\theta} = 0.167$, the steady-state level of crime-specific human capital, $\tilde{H}^C = 5.133$. From (44), by normalizing the steady-state wage rate to unity, $\tilde{w} = 1$, the efficiency of investment in legal human capital is then calculated, $\Theta^N_0 = 0.215$. For crime-specific human capital, we set the investment efficiency to be twice of $\Theta^N_0$, where $\Theta^C_0 = 0.43$. The time-invariant additive parameter of crime-specific human capital, $\Lambda$, is therefore 0.258.

Next, we consider the production side. The parameters in the production function, (20), is parameterized in the standard manner, in that, the share of physical capital, $\alpha = 0.35$, and share of effective labor, $1 - \alpha = 0.65$, are based on the production shares of the respective input. The average productivity parameter, $A$, is normalized to one, as in Tayler and Zilberman (2016). From IMF Capital Stock Database, the average final output-to-physical capital ratio of our sample economies is 0.451. From Appendix B, we know that $\tilde{r} = \frac{\tilde{\alpha} \tilde{Y}}{(1 + \tilde{\theta} \tilde{H}^C)^K \left( \frac{\tilde{\nu} - 1}{\tilde{\sigma}} \right)}$, which then allows us to calculate the elasticity of demand.
for intermediate goods, $\zeta = 2.43$, implying a high mark-up rate of 70 percent. This is relatively high but does illustrate a case where firms would need a higher mark-up in the presence of additional cost associated with illegal extortions.

In terms of the parameters characterizing commercial banks’ lending, following Agénor and Alper (2012), we set the effective collateral-loan ratio, $\kappa = 0.2$, and the elasticity of the risk premium with respect to collateral, $\phi_1 = 0.05$. We also set the elasticity of the risk premium with respect to the economy-wide crime rate to be the same, $\phi_2 = 0.05$. For the other parameters, first, from the World Bank World Development Indicators, note that the average lending interest rate for our 21 sample economies during the period 1991-2016 is 22 percent, while the average risk premium on lending is 17.2 percent. Using the steady-state relationship, $\bar{\iota}_L = (1 + \frac{1}{\eta_{Lq}})^{-1}q_0^{-1}[1 + \Psi_0(\frac{\bar{K}}{T})^{\phi_1}(\bar{\theta})^{\phi_2}]\bar{r}$, assuming $\eta_{Lq} = 1$, base repayment probability, $q_0$, of 0.2, and given the initial values of the endogenous variables, the risk premium parameter, $\Psi_0$, is calculated to be 0.815.

For the central bank, we follow Agénor and Alper (2012) and Agénor et al. (2014) by setting initial reserve requirement ratio, $\mu$, to a relatively low rate of 10 percent. Given this, and that $\bar{\iota}_D = (1 - \mu)\bar{r}$, we have the steady-state deposit rate, $\bar{\iota}_D = 0.045$. For the monetary policy, the smoothing parameter is set at $\varpi = 0$. We also set $\epsilon_1 = 1.5$ and $\epsilon_2 = 0.2$, which is consistent with Liu (2006) and Moura and Carvalho (2010). The latter, $\epsilon_2$, in particular, is consistent with evidence reported for several countries in Latin America. For the rule-based specification for public expenditure on public order and safety, $(??)$, the parameter, $\psi_1$, which models the responsiveness of the spending with respect to a deviation in crime rate from its steady state, is set at 0.1. Finally, for the stochastic shocks, we specify all four as first-order autoregressive processes with a common degree of persistence, $\zeta_A = \zeta_M = \zeta_C = \zeta_N = 0.8$. 

24
5 Policy Experiments

As alluded, our main objective involves examining how the approach to macroeconomic stabilization would differ in an economy with crime and formal educational quality uncertainty. Given the intricate relationship between the two, we also explore for any potential role of police spending in stabilization. First, we consider a temporary shock to formal human capital investment, or specifically, a 10 percent standard deviation shock to $\epsilon_t^N$. From (7), this reflects a quality uncertainty to households’ investment in formal human capital, albeit an upside shock. The impulse responses are presented in Figure 2, which in addition to the benchmark, also illustrates scenarios of (i) an economy with less crime (household spend 5 percent less of their time in criminal activities, $\bar{\theta} = 0.117$), (ii) higher (quadruple) base efficiency level of formal human capital investment, $\Theta_0^N$, and (iii) a higher (double) initial share of spending on public order and safety, $v_P$.

As expected, we see that formal market works and formal human capital level respond positively, which in turn leads to higher production and consumption. With the temporary uptick in investment efficiency, individuals reduce their asset-holdings, including government bonds, and invest more in human capital. The expansionary effects on production also result in greater opportunities for extortions, which translate to a general equilibrium effect of a higher level of crime-specific human capital. In comparison to an economy with lower steady-state crime rate, we see that the procyclicality effect on formal human capital, market works, and output is lower. In other words, the initial level of crime reduces the procyclicality effect of formal human capital investment, with slightly higher degree of persistence in the response of output and inflation. In fact, a positive shock to formal human capital investment efficiency also raises the level of

\[^{13}\]Indeed, a quick deterministic analysis of a steady-state increase in the share of police spending, $v_P$, will lead to higher levels of formal human capital, final output, consumption, and lower level of crime-specific human capital in the new steady state. These therefore reaffirms the long-run positive effects of police spending commonly documented in the literature. The results of this analysis is not presented to save space.
illegal human capital, and this co-movement appears to be independent of the initial level of police spending. This co-movement appears to partly explain the experience in some Latin American economies over the past decades: In spite of increasing policy efforts in promoting formal education, crime rate appears to persist.

Next, we explore the role of police spending further. Suppose for the same temporary $\epsilon_t^N$ shock, we undertake a standard “rule versus discretion” exercise by comparing the impulse responses of the benchmark model (discretionary approach to police spending by setting $u_P$) and the model with reactionary rule. These, together with selected sensitivity analysis scenarios, are presented in Figure 3. While Figure 2 initially suggests that the initial level of police spending is immaterial in curbing the accumulation of crime-specific human capital, we notice in Figure 3 that the use of a spending rule significantly increases its policy effectiveness. Indeed, when compared to a discretionary allocation tied to the output level, the presence of a reactionary rule reduces the cyclical effects associated with the fluctuation in educational quality, while gaining more in formal human capital investment, formal works, output and consumption over a longer period. These, coupled with the “de-coupling” of the shock’s influence on illegal human capital, suggest a potentially useful rule-based approach to police spending allocation, especially in an economy with significant organized crime and educational quality uncertainty.

Next, we examine the model properties by stimulating a temporary 10 percent structural shock in increasing the effectiveness of expenditure on police spending, $\epsilon_t^C$. The impulse responses for both the benchmark and rule-based specification, along with the sensitivity analysis scenario of a higher base efficiency ($\Theta_0^C$), are presented in Figure 4. Unlike the marked difference observed for the $\epsilon_t^N$ shock in Figure 3, the policy effects for this specific shock are numerically insignificant. This is likely due to the unit of measurement of crime rate being small, $\theta_t \in (0, 1)$, which as a ratio to its steady state, means any relative deviation will be small. In the absence of a very large $\psi_1$ elasticity
value, the responses of other variables are therefore small. Nevertheless, within this context, we still find consistency to previous results, in that, the efficiency and the level of the expenditure have very small effect in curbing accumulation of illegal human capital, though the greater stabilization properties of a rule-based approach can negate this to an extent.

Based on the two structural shocks considered, while the difference appears to be trivial if we only concern about fluctuations in the efficiency of the specific spending, a policy rule to police spending allocation can have a stabilization role if the policymaker is concerned about smoothing the effects of shocks arisen from formal educational uncertainty, while simultaneously achieving a “de-coupling” of the shock’s positive influence on illegal human capital accumulation.

To examine further the properties of the rule-based approach to police spending, we study the remaining two shocks (monetary and productivity), with the impulse responses illustrated in Figure 5 and Figure 6. In Figure 5, we observe the well-documented “financial accelerator” effect, where credit imperfection in the model causes the impact of monetary shocks on prices to magnify. While a rule-based approach to police spending remains effective in de-coupling the illegal human capital accumulation process from the procyclical formal human capital, it appears to exacerbate the financial accelerator effect, in that the response of prices to the monetary shock is greater beyond the initial 10 periods, with the propagation process appears to have a greater degree of inertia.

Lastly, in Figure 6, when experimenting with a positive productivity shock, we observe similar patterns in the impulse responses. While a rule-based approach has better output stabilization property in the short-term horizon (first 20 periods) than even some instances of conventional interest-rate smoothing regime, such a regime also imparts greater degree of inertia to the adjustment process. In the medium-term, it underperforms conventional monetary smoothing. This suggests that, while a rule-based
police spending might be effective in supporting formal human capital investment (by smoothing out the fluctuation associated with educational quality uncertainty), as well as decoupling the cyclical properties of formal and illegal human capital accumulation, it comes at a cost of imparting greater inertia to the adjustment process. As such, instead of replacing the role of conventional monetary policy, the use of a more systematic reaction rule to police spending allocation in stabilizing shocks to formal human capital investment would necessarily require a supplementary monetary smoothing to reduce the adverse financial accelerator effect brought about by such a regime.

6 Concluding Remarks

We develop a DSGE model to examine the effects of quality uncertainty in human capital investment in an economy with crime, differential human capital, police spending (generally, public expenditure on public order and security), credit market imperfection, and monetary policy. The latter duo are common features in “financial accelerator” models, therefore allow for more realistic modeling of the impact of crime on businesses and the wider economy, which in turn facilitate better understanding of the macroeconomic stabilization properties of a policy such as the police spending. The model is parameterized illustratively for a stylized middle-income Latin American economy where criminal activities are a significant part of society. The main innovation of our study is that we explicitly consider the different potential role of public spending on public order and safety, beyond its generally assumed function of crime reduction.

Based on our analysis, in a model economy with organized crime, the accumulation processes of formal and illegal human capital tend to share the same cyclical properties, hence contributing to the persistency in crime rate. In order for formal education to achieve its desired role in reducing crime [as suggested in Pressman (2008) and Machin
et al. (2012)], there appears to be a need for the adoption of a rule-based approach to police spending allocation. Such a policy regime not only smoothens out the fluctuations arisen from formal educational uncertainty, but also contributes to a “decoupling” of the common cyclical properties of the two types of human capital. This suggests that, in an economy with persistently high crime rate, a more systematic fiscal allocation to expenditure on public security/police may be warranted. Nevertheless, the use of a rule-based approach does come with the cost of it imparting a greater degree of inertia onto more conventional business-cycle shocks, and potentially worsening the financial accelerator effect arisen from credit market imperfections. This means the use of a more systematic reaction rule to police spending allocation in stabilizing shocks to formal human capital investment would necessarily require a supplementary interest-rate smoothing regime to negate these negative effects.

For future research direction, we acknowledge the limitations of our analysis due to the uneven quality of crime data. With longer time series, the heterogeneous nature of the different Latin American economies can be accounted for by either Bayesian-estimating our theoretical model, or evaluating the properties of the model solutions in a DSGE-vector autoregression (DSGE-VAR) examination. In terms of theoretical modeling, it is also worth pointing out that neither the issue of income inequality nor other demographic factors known to cause violent crime are explored (see, for example, Fajnzylber et al., 2002). These are issues worth-exploring in further theoretical studies, perhaps in a model without the credit and monetary features introduced in this study.
